Evaluation of Previous Rotation on Flax Performance in Certified Organic Production - Crawfordsville Trial, 2005

Abstract

Flax (*Linum usitatissimum* [Linaceae] – linen family) is an ancient crop that had been grown in Iowa for many years, but it has been displaced by the emphasis on commodity corn and soybeans. Flax has many uses, including industrial oils from oilseed flax; food-quality flaxseed oil; and linen products, fiberboard and paper products from the straw. Flaxseed oil is high in omega-3 fatty acids, which are associated with lowered risk of heart disease and lowered blood cholesterol levels. Flax has a 50-day vegetative period, a 25-day flowering period, and a 35-day period to maturity. Seeds are produced in bolls that contain 6–10 seeds. Seed color can be brown, golden, or yellow. The seed is covered with a mucilaginous coating. The flax crop responds to up to 50 lb/acre nitrogen, similar to organic small grains. Mycorrhizal association may increase the ability of flax to take up phosphorus from the soil, so growing flax after mycorrhizal wheat rather than after nonmycorrhizal canola may improve its phosphorus uptake by flax. Early-seeded flax generally produces the highest yields, when using the same planting dates as small grains. Frost seldom kills flax seedlings. Nonuniform maturity and ripening are problems in late-seeded fields.

Introduction

Flax (Linum usitatissimum [Linaceae] – linen family) is an ancient crop that had been grown in Iowa for many years, but it has been displaced by the emphasis on commodity corn and sovbeans. Flax has many uses, including industrial oils from oilseed flax; food-quality flaxseed oil; and linen products, fiberboard and paper products from the straw. Flaxseed oil is high in omega-3 fatty acids, which are associated with lowered risk of heart disease and lowered blood cholesterol levels. Flax has a 50-day vegetative period, a 25-day flowering period, and a 35-day period to maturity. Seeds are produced in bolls that contain 6–10 seeds. Seed color can be brown, golden, or yellow. The seed is covered with a mucilaginous coating. The flax crop responds to up to 50 lb/acre nitrogen, similar to organic small grains. Mycorrhizal association may increase the ability of flax to take up phosphorus from the soil, so growing flax after mycorrhizal wheat rather than after nonmycorrhizal canola may improve its phosphorus uptake by flax. Early-seeded flax generally produces the highest yields, when using the same planting dates as small grains. Frost seldom kills flax seedlings. Nonuniform maturity and ripening are problems in lateseeded fields.

In 2003, an organic flaxseed oil–processing facility began operations in Iowa. With the introduction of this plant and a possible worldwide market for flaxseed oil came a need for increased organic flax production in Iowa.

Materials and Methods

In the Crawfordsville organic flax trial, Norlin flax was seeded on March 29-30, 2005, at 60 lb/acre with multi-year red clover underseeded at 14 lb/acre. Flax was seeded into three blocks: 2004 crop of corn; 2004 crop of soybean; and 2004 crop of barley/red clover. Flax plant populations were counted on May 25 and flax height and weed populations were counted on May 25 and June 29, 2005. Flax height was taken by measuring three random plants in each plot. Flax population counts were taken by placing a 1-ft² quadrat in three areas of each plot and counting the number of plants inside the quadrat. Weed counts were taken by placing a 1-m² quadrat in three areas of each plot and counting the number of broadleaf and grass weeds. Biomass samples were taken by randomly clipping three 1-ft² sections from each plot on June 1 and July12. The biomass samples were weighed and separated into flax, red clover, and weeds; then they were placed in a dryer at 155°F for 48 hours, after which time separate dry weights were taken for each group. Twelve random $1-ft^2$ flax harvest plots per block were cut at ground level and hand-threshed on July 25. The remainder of the flax was harvested with a combine on July 25–29, 2005. Soil samples were taken on June 1 and August 11, 2005, from five random locations within each plot at a depth of 6 in.

Results and Discussion

Yields were significantly different based on the crop of the previous year. The flax field that was in barley/red clover in 2004 yielded 33.14 bushels/acre, followed by the flax that was in soybean (25.79 bu/acre), and finally the flax that followed corn (13.60 bu/acre) (Table 1). Stand counts were higher in the flax following soybean than in flax following corn and barley/red clover, which had similar stand

counts (Table 1). Red clover biomass was higher in the flax following soybeans than the other two trials (Table 1). No significant difference was observed in plant height on May 25, but on June 29, the flax following corn was found to be significantly shorter than the other two varieties (Table 1). The flax following barley/red clover had significantly higher flax biomass (Table 1) despite having higher numbers of grass weeds than the other two blocks (Table 2). Broadleaf weeds (mainly lamb's quarters) were more abundant in the flax following corn than in the other two trials, however, and contributed to the greatest weed biomass (Table 2). Significantly higher levels of NO₃-N were found in soils where barley/red

clover were grown in 2004. Recommendations from this study include the need for a nitrogenfixing crop in the rotation prior to flax planting for maximum yield.

Acknowledgments

We would like to thank the Leopold Center for Sustainable Agriculture and Mary Wiedenhoeft (Agronomy Department, ISU) for their support of this project. Thanks go to Mark and Julie Schuett of BIOWA Nutraceuticals, Cherokee, IA, and Spectrum Organic Products, Petaluma, CA, for supplying seed and assistance with this project. Thanks also go to Alzbeta Novotna for her help on production, data collection, and analytical aspects of this project.
